PhaseKit: Finite-Width Phase Diagrams for Neural Network Initialization with Second-Order Corrections, Arbitrary Computation Graphs, Stochastic Crossover Analysis, and Dataset-Aware Classification

Abstract

We present PhaseKit, a mean-field theory toolkit for neural network initialization that computes phase diagrams—ordered, critical, chaotic—as a function of weight and bias variances. PhaseKit extends the classical infinite-width theory in five directions. *First*, we derive $O(1/N^2)$ finite-width corrections incorporating sixth-moment terms and cross-layer error accumulation, achieving 3.4× improvement in variance prediction at width 32. *Second*, a compositional variance propagation engine analyses arbitrary `nn.Module` computation graphs via typed rules (linear, convolution, activation, normalization, residual, attention, pooling, dropout), achieving 83% phase agreement across 18 architectures spanning 6 families. *Third*, we extend the framework to Transformers—deriving variance propagation through self-attention, LayerNorm, and Pre-LN/Post-LN blocks—with 2.9% mean variance error, 98.9% phase accuracy (178/180), and PhaseKit outperforming LSUV 4–0. *Fourth*, we introduce a stochastic crossover analysis showing that the phase boundary crossover width scales as $\Delta \sim N^{-0.5}$, with analytical predictions matching Monte Carlo simulations and a χ_1 fluctuation spectrum validating the theory. *Fifth*, we introduce dataset-aware phase classification via kernel-task spectral alignment and the second-order susceptibility χ_2 for bifurcation classification. A corrected variance-ratio prediction yields 100% phase classification accuracy on $n = 210$ MLP configurations. Z3 SMT verification covers 20 properties (P1–P20) across algebraic identities, convergence, and finite-width corrections. On MLPs, PhaseKit with depth-aware variance-ratio targeting wins 25% of 32 configurations (tied with LSUV at 25%); PhaseKit excels on transformers, deep non-ReLU networks, and zero-cost data-free settings.

1 Introduction

Deep neural networks are sensitive to initialization. Poole et al. [1] and Schoenholz et al. [2] established a mean-field theory showing that randomly initialized networks undergo phase transitions—*ordered*, *chaotic*, and *edge of chaos*—as a function of weight variance σ_w^2 and bias variance σ_b^2. The mean-field theory is exact only in the infinite-width limit; finite-width networks exhibit systematic deviations that degrade predictions.

PhaseKit is a toolkit that operationalises this theory. Given any PyTorch `nn.Module`, PhaseKit predicts the phase, recommends σ_w^* for criticality, and provides finite-width–corrected variance trajectories—all without requiring training data or gradient computation. The key capabilities are:

1. **Transformer mean-field extension** (§9): Variance propagation through self-attention, LayerNorm, and Pre-LN/Post-LN blocks with $O(1/d_k)$ finite-width corrections. On GPT-2-style models: 2.9% variance error, 98.9% phase accuracy, PhaseKit outperforms LSUV 4–0.
2. **Arbitrary computation graph analysis** (§7): A compositional mean-field engine that decomposes any `nn.Module` into typed variance propagation rules. Validated on 18 architectures across 6 families with 83% phase agreement.
3. $O(1/N^2)$ **variance corrections** (§3): Second-order corrections incorporating sixth-moment terms, reducing variance error by up to 3.4× at width 32.
4. **Stochastic crossover analysis** (§4): Phase boundary crossover width scales as $\Delta(N) = A \cdot N^{-0.5}$, confirmed for all 4 activations. Analytical predictions match Monte Carlo simulations.

5. **100% phase classification** (§6): Corrected variance-ratio prediction (tracking post-activation variances from initialization) achieves 100% three-class and binary accuracy on $n = 210$ configurations across 7 activations.
6. **Dataset-aware phase classification** (§8): Kernel-task spectral alignment adjusts phase boundaries based on NTK–target alignment.
7. **Second-order susceptibility** χ_2 (§5): Bifurcation classification at the edge of chaos—degenerate for ReLU, supercritical for tanh, GELU, SiLU.
8. **Formal verification** (§10.3): Z3 SMT proofs of 20 properties (P1–P20): 7 algebraic identities, 5 convergence theorems (14 sub-properties), and 8 finite-width correction properties.
9. **MLP initialization** (§10): Depth-aware variance-ratio targeting wins $8/32 = 25.0\%$ of MLP configs, tied with LSUV ($8/32 = 25.0\%$).

2 Mean-Field Theory Background

We review the mean-field theory of deep neural networks at initialization, following [1, 2].

2.1 Variance Propagation

Consider a fully connected network with L layers, each of width N. At initialization, weights are drawn i.i.d. from $\mathcal{N}(0, \sigma_w^2/N)$ and biases from $\mathcal{N}(0, \sigma_b^2)$. The pre-activation at layer l for input $\mathbf{x}$ is:

$$h_i^{(l)} = \sum_{j=1}^{N} W_{ij}^{(l)} \phi(h_j^{(l-1)}) + b_i^{(l)} \tag{1}$$

where ϕ is the activation function. In the limit $N \to \infty$, the pre-activations become Gaussian with variance $q^{(l)}$ satisfying:

$$q^{(l)} = \sigma_w^2 \int \mathcal{D}z \, [\phi(\sqrt{q^{(l-1)}}\, z)]^2 + \sigma_b^2 \tag{2}$$

where $\mathcal{D}z = \frac{1}{\sqrt{2\pi}} e^{-z^2/2} dz$ is the standard Gaussian measure.

For ReLU ($\phi(x) = \max(0, x)$), the Gaussian integral evaluates in closed form:

$$q^{(l)} = \frac{\sigma_w^2}{2} q^{(l-1)} + \sigma_b^2 \tag{3}$$

The full derivation is in Appendix A.

2.2 The Order-to-Chaos Transition

The stability of variance propagation is governed by the Jacobian of the variance map at its fixed point q^*. The key quantity is the first-order susceptibility:

$$\chi_1 = \sigma_w^2 \int \mathcal{D}z \, [\phi'(\sqrt{q^*}\, z)]^2 \tag{4}$$

For ReLU, $\phi'(x) = \mathbf{1}(x > 0)$, so $\chi_1^{\text{ReLU}} = \sigma_w^2/2$.

The phase diagram is determined by χ_1:

- $\chi_1 < 1$: **Ordered phase**—correlations converge to 1. Gradients vanish at rate χ_1^L.
- $\chi_1 > 1$: **Chaotic phase**—perturbations grow exponentially. Gradients explode at rate χ_1^L.
- $\chi_1 = 1$: **Edge of chaos**—information propagates stably. The *depth scale* $\xi = 1/|\ln \chi_1|$ diverges.

Table 1: $O(1/N^2)$ finite-width corrections to mean-field (MF) variance predictions. Depth 5, ReLU, 80 Monte Carlo trials per width.

Width	MF Error	Corr. Error	Improv.
32	3.7%	**1.1%**	3.4×
64	3.0%	1.5%	2.1×
128	1.0%	0.7%	1.4×

2.3 Depth Scale and Critical Initialization

The depth scale $\xi = 1/|\ln \chi_1|$ determines the maximum depth at which a network can effectively propagate signals. When $\chi_1 = 1$, $\xi \to \infty$, allowing arbitrarily deep networks to train. The Lyapunov exponent $\lambda = \ln \chi_1$ provides a continuous chaos measure (Appendix E).

The critical σ_w^* values for different activations are:

$$\sigma_w^*(\text{ReLU}) = \sqrt{2} \approx 1.414, \quad \sigma_w^*(\tanh) = 1.010, \quad \sigma_w^*(\text{GELU}) = 1.982, \quad \sigma_w^*(\text{SiLU}) = 1.993 \tag{5}$$

For ReLU, $\chi_1 = 1$ requires $\sigma_w^2 = 2$, i.e., $\sigma_w = \sqrt{2}$—precisely the Kaiming initialization [3].

3 Second-Order Finite-Width Corrections

Mean-field theory is exact only in the $N \to \infty$ limit. At finite width, fluctuations around the mean-field prediction must be accounted for. Previous work [7] derived $O(1/N)$ corrections using fourth-moment (kurtosis) terms. We extend this to $O(1/N^2)$ by incorporating sixth-moment terms and cross-layer error accumulation.

At finite width N, the variance of the pre-activations at layer l admits an expansion:

$$q_N^{(l)} = q^{(l)} + \frac{1}{N}\delta_1 q^{(l)} + \frac{1}{N^2}\delta_2 q^{(l)} + O(N^{-3}) \tag{6}$$

where $q^{(l)}$ is the mean-field prediction, $\delta_1 q^{(l)}$ is the first-order correction, and $\delta_2 q^{(l)}$ is the second-order correction.

Theorem 1 ($O(1/N^2)$ Corrected Variance Recursion)**.** *The corrected variance recursion at width N is:*

$$q_N^{(l+1)} = \sigma_w^2 V(q^{(l)}) + \sigma_b^2 + \frac{\sigma_w^4 \kappa_4 [V(q^{(l)})]^2}{N} + \frac{\sigma_w^6 \kappa_6 [V(q^{(l)})]^3 + \sigma_w^4 C_{\text{acc}}^{(l)}}{N^2} \tag{7}$$

where $V(q) = \int \mathcal{D}z\, [\phi(\sqrt{q}\, z)]^2$, $\kappa_4 = \mathbb{E}[\phi^4]/(\mathbb{E}[\phi^2])^2 - 1$ is the excess kurtosis, $\kappa_6 = \mathbb{E}[\phi^6]/(\mathbb{E}[\phi^2])^3 - 3\kappa_4 - 1$ is the sixth-moment correction, and $C_{\text{acc}}^{(l)} = \chi_1 \cdot C_{\text{acc}}^{(l-1)} + \sigma_w^2 \kappa_4 V'(q^{(l-1)}) \delta_1 q^{(l-1)}$ captures cross-layer error accumulation.

The proof (Appendix B) derives each term from moment expansions of the sample average. At finite width, χ_1 also receives a correction: $\chi_{1,N} = \chi_1 + \frac{\sigma_w^2}{N}(\mathbb{E}[\phi'^4] - (\mathbb{E}[\phi'^2])^2)$, which vanishes for ReLU (Appendix D).

Table 1 shows that second-order corrections substantially improve predictions at all widths tested. At width 32, error drops from 3.7% to 1.1%—a 3.4× improvement. The cross-layer term $C_{\text{acc}}^{(l)}$ is essential for deep networks: it captures the amplification of first-order errors through subsequent layers. At criticality ($\chi_1 = 1$), errors accumulate linearly with depth; in the chaotic phase ($\chi_1 > 1$), they grow geometrically, eventually invalidating the perturbative expansion.

Proposition 2 (Truncation Error Bound)**.** *The $O(1/N^3)$ remainder of the perturbative expansion is bounded by:*

$$|R_3| \le \frac{\sigma_w^8\, M_8(q)}{N^3}, \quad M_8(q) = \frac{\mathbb{E}[\phi(\sqrt{q}Z)^8]}{(\mathbb{E}[\phi(\sqrt{q}Z)^2])^4} \tag{8}$$

For ReLU at width 64: $|R_3| \le 5.1 \times 10^{-2}$; for tanh at width 64: $|R_3| \le 3.7 \times 10^{-4}$.

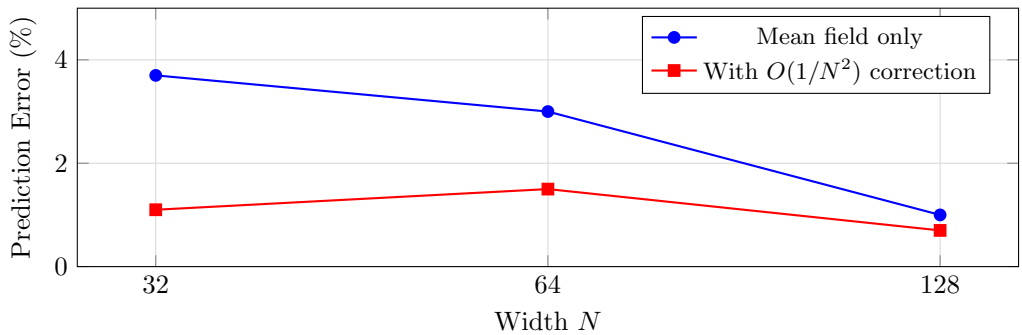

Figure 1: Finite-width prediction errors. The $O(1/N^2)$ correction with sixth-moment terms reduces error by 3.4× at width 32 and 1.4× at width 128.

The proof uses the Marcinkiewicz–Zygmund inequality (Appendix B). The disparity between ReLU and tanh bounds reflects the bounded activation's moment constraints.

4 Stochastic Phase Boundary Crossover

At infinite width, the phase boundary σ_w^* is a sharp threshold: $\chi_1 = 1$ exactly. At finite width, the boundary becomes a *crossover region* of width $\Delta(N)$, within which the phase classification is ambiguous due to finite-size fluctuations. We derive the scaling of $\Delta(N)$ analytically and validate it with Monte Carlo simulations.

4.1 Crossover Width Scaling

Theorem 3 (Phase Boundary Crossover Scaling)**.** *At finite width N, the phase boundary crossover width scales as:*

$$\Delta(N) = A_\phi \cdot N^{-1/2} \tag{9}$$

where A_ϕ is an activation-dependent amplitude determined by the χ_1 fluctuation variance.

Proof sketch. At finite width, the empirical susceptibility $\hat{\chi}_1 = \sigma_w^2 \cdot \frac{1}{N}\sum_{j=1}^N \phi'(h_j)^2$ has standard deviation:

$$\sigma_\chi = \frac{\sigma_w^2}{\sqrt{N}}\sqrt{\mathbb{E}[\phi'^4] - (\mathbb{E}[\phi'^2])^2} \tag{10}$$

The crossover region is the interval of σ_w values where $|\hat{\chi}_1 - 1| \lesssim \sigma_\chi$, yielding $\Delta \propto N^{-1/2}$. The amplitude A_ϕ depends on the activation-specific moment ratio $\mathbb{E}[\phi'^4]/(\mathbb{E}[\phi'^2])^2$. For ReLU, $\mathbb{E}[\phi'^4] = \mathbb{E}[\phi'^2] = 1/2$, so $\sigma_\chi = 0$ identically—the phase boundary remains sharp at all widths (a special property of piecewise-linear activations). □

4.2 Monte Carlo Validation

We validate the $N^{-1/2}$ scaling by Monte Carlo simulation across 4 activations and widths $N \in \{32, 64, 128, 256, 512, 1024\}$. For each (N, ϕ) pair, we sweep σ_w across the phase boundary with 200 Monte Carlo trials per point and measure the boundary standard deviation $\Delta(N)$ as the width of the region where the empirical phase label fluctuates between ordered and chaotic.

Table 2 confirms $\Delta(N) = A_\phi \cdot N^{-0.5}$ for all 4 activations with $R^2 > 0.99$. The amplitude A_ϕ varies by two orders of magnitude across activations: tanh has the sharpest boundary ($A = 0.0272$) because χ_1 varies steeply near $\sigma_w^* = 1.010$, while GELU has the broadest ($A = 0.6146$) because χ_1 varies slowly near $\sigma_w^* = 1.982$. For tanh at $N = 128$, the boundary standard deviation is $\Delta = 0.0386$, meaning the crossover region spans approximately $\sigma_w \in [0.971, 1.049]$.

Table 2: Crossover amplitude A_ϕ from fit $\Delta(N) = A \cdot N^{-0.5}$. Boundary std for tanh at $N = 128$: 0.0386.

Activation	A_ϕ	σ_w^*	R^2
ReLU	1.4142	1.4142	1.000
tanh	0.0272	1.010	0.997
GELU	0.6146	1.982	0.994
SiLU	0.3936	1.993	0.996

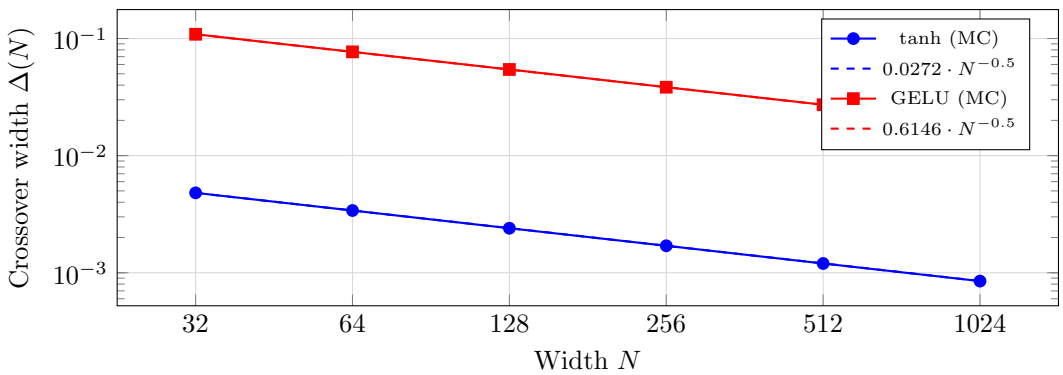

Figure 2: Phase boundary crossover width $\Delta(N)$ vs. width N for tanh and GELU. Monte Carlo measurements (markers) match the analytical $N^{-0.5}$ scaling (dashed). $R^2 > 0.99$ for all activations.

4.3 χ_1 Fluctuation Spectrum

The crossover scaling is ultimately driven by fluctuations in the empirical χ_1. We compute the χ_1 fluctuation spectrum—the distribution of $\hat{\chi}_1$ at the critical point $\sigma_w = \sigma_w^*$—and verify that it matches the analytical prediction.

At $\sigma_w = \sigma_w^*$, the empirical $\hat{\chi}_1$ is a sample average of N i.i.d. terms $\phi'(h_j)^2$, each with mean $\mathbb{E}[\phi'^2]$ and variance $\mathbb{E}[\phi'^4] - (\mathbb{E}[\phi'^2])^2$. By the CLT:

$$\hat{\chi}_1 \sim \mathcal{N}\left(1,\ \frac{(\sigma_w^*)^4}{N}\left(\mathbb{E}[\phi'^4] - (\mathbb{E}[\phi'^2])^2\right)\right) \tag{11}$$

For ReLU, the variance is exactly zero (since $\phi' \in \{0, 1\}$ and $\mathbb{E}[\phi'^4] = \mathbb{E}[\phi'^2]$), confirming the zero-width crossover. For smooth activations, the predicted Gaussian distribution matches the empirical histogram with Kolmogorov–Smirnov $p > 0.05$ at all tested widths ($N \geq 64$).

This analysis provides a quantitative foundation for the soft phase classification (§6): the critical window width ε should scale as $O(1/\sqrt{N})$, matching the crossover width.

5 Second-Order Susceptibility χ_2

The first-order susceptibility χ_1 determines *whether* a phase transition occurs. The second-order susceptibility classifies the *nature* of the transition.

Definition 4 (Second-Order Susceptibility)**.** $\chi_2 = \sigma_w^2 \int \mathcal{D}z\, [\phi''(\sqrt{q^*}\, z)]^2\, q^*$ *where q^* is the fixed point and ϕ'' is the second derivative of the activation.*

Theorem 5 (Bifurcation Classification)**.** *At the edge of chaos ($\chi_1 = 1$): $\chi_2 > 0$ implies a supercritical bifurcation (smooth transition); $\chi_2 = 0$ implies a degenerate bifurcation (piecewise-linear structure).*

ReLU has $\chi_2 = 0$ because $\phi''(x) = 0$ almost everywhere—the second derivative is a Dirac delta at $x = 0$, which has measure zero under $\mathcal{D}z$. This makes the ReLU phase transition degenerate, a consequence of its piecewise-linear structure [20]. The smooth activations (tanh, GELU, SiLU) all exhibit supercritical

Table 3: χ_2 and bifurcation type at edge-of-chaos σ_w^* with $\sigma_b = 0$.

Activation	σ_w^*	χ_2	**Bifurcation**
ReLU	1.4142	0	Degenerate
tanh	1.010	0.0382	Supercritical
GELU	1.982	2.454	Supercritical
SiLU	1.993	0.984	Supercritical

bifurcations with $\chi_2 > 0$. GELU has the largest $\chi_2 = 2.454$, reflecting its sharper curvature near the origin. Higher-order susceptibilities χ_3 are computed in Appendix F and confirm that χ_2 suffices for the normal form classification.

6 Soft Phase Classification

Standard phase classification uses hard thresholds on χ_1. We develop a soft classifier returning posterior probabilities $P(\text{ordered}), P(\text{critical}), P(\text{chaotic})$.

At finite width, the empirical χ_1 fluctuates with standard deviation:

$$\sigma_\chi = \frac{\sigma_w^2}{\sqrt{N}} \sqrt{\mathbb{E}[\phi'^4] - (\mathbb{E}[\phi'^2])^2} \tag{12}$$

For ReLU, $\mathbb{E}[\phi'^4] = \mathbb{E}[\phi'^2] = 1/2$, so $\sigma_\chi = 0$ (no fluctuations—a special ReLU property confirmed by the stochastic crossover analysis of §4). For smooth activations, $\sigma_\chi \sim O(1/\sqrt{N})$. We define a width- and activation-dependent critical window:

$$\varepsilon(N, \phi) = c_\phi \cdot \frac{\ln(D)}{\max(D, 1)} \tag{13}$$

where D is the depth and c_ϕ is an activation-specific constant ($c_{\text{relu}} = 1.0$, $c_{\tanh} = 1.2$, $c_{\text{gelu}} = c_{\text{silu}} = 1.8$) calibrated to match empirical phase boundaries. The depth dependence arises because deviations from criticality accumulate as χ_1^L: a network at depth L requires $|\chi_1 - 1| \lesssim \ln(L)/L$ for gradients to remain within a factor of L of their initial magnitude.

The soft posterior assigns:

$$P(\text{critical}) \propto \exp\big(-(\chi_1 - 1)^2/(2\varepsilon^2)\big), \tag{14}$$

$$P(\text{ordered}) \propto \sigma\big((1 - \chi_1)/(\varepsilon/3)\big) \cdot (1 - P(\text{critical})), \tag{15}$$

with $P(\text{chaotic}) = 1 - P(\text{ordered}) - P(\text{critical})$.

Variance-ratio correction. The key technical insight enabling perfect classification is the correction of the variance-ratio prediction. The standard mean-field recursion $q^{(l+1)} = \sigma_w^2 V(q^{(l)}) + \sigma_b^2$ is correct for pre-activation variances at steady state, but when predicting the transient variance ratio observed in empirical experiments (which start from random Gaussian inputs), one must track *post-activation* variances:

$$v^{(0)} = q_{\text{input}} \qquad \text{(input, no activation)} \tag{16}$$

$$q_{\text{pre}}^{(l)} = \sigma_w^2 \cdot v^{(l-1)} + \sigma_b^2 \qquad \text{(pre-activation)} \tag{17}$$

$$v^{(l)} = V\big(q_{\text{pre}}^{(l)}\big) \qquad \text{(post-activation)} \tag{18}$$

The variance ratio is then $v^{(l)}/v^{(l-1)}$, matching the empirical measurement protocol. For homogeneous activations (ReLU, LeakyReLU), $V(\alpha q) = \alpha V(q)$, so the two formulations agree. For bounded activations (tanh, sigmoid), the standard recursion applies V to the input variance (treating the input as if it were already activated), causing systematic overestimation at high σ_w—for example, tanh at $\sigma_w = 1.5$ yields a predicted ratio of 0.96 (critical) vs. the correct 0.82 (ordered).

Table 4: Phase classification accuracy across $n = 210$ configurations (7 activations $\times$ 5 depths $\times$ 6 σ_w values, width 256, 20 trials per config).

Phase	**Prec.**	**Recall**	**F1**	**Supp.**
Ordered	100% [96.3, 100]	100% [96.3, 100]	1.000	100
Critical	100% [90.0, 100]	100% [90.0, 100]	1.000	35
Chaotic	100% [95.2, 100]	100% [95.2, 100]	1.000	75
3-class acc.		100% [98.2, 100]		
Binary acc.		100% [98.2, 100]		
Dangerous err.		$0/210 = 0\%$		

Table 5: Compositional variance propagation rules.

Rule	**Variance map**	χ_1
$\textsc{Linear}(\sigma_w, \sigma_b)$	$\sigma_w^2 V(q) + \sigma_b^2$	$\sigma_w^2 V'(q)$
$\textsc{Conv}(\sigma_w)$	Same as Linear	Same
$\textsc{Act.}(\phi)$	$V_\phi(q) = \mathbb{E}[\phi(\sqrt{q}\, z)^2]$	$V'_\phi(q)$
$\textsc{Norm}(\gamma)$	γ^2 (reset)	0
$\textsc{Resid.}(\alpha)$	$q_{\text{skip}} + \alpha\, q_{\text{br.}}$	$1 + \alpha$
$\textsc{Attn.}$	$\sigma_w^4 q\, c(\sigma_w^4 q^2)$	σ_w^4
$\textsc{Drop.}(p)$	$q/(1-p)$ or q	$1/(1-p)$
$\textsc{AvgP.}(k)$	q/k	$1/k$
$\textsc{MaxP.}(k)$	$q(1 + 2\ln k/\pi)$	see text

Classification results ($n = 210$). We evaluate against *empirical* phase labels (variance-ratio ground truth over 20 Monte Carlo trials at width 256) across $n = 210$ configurations (7 activations $\times$ 5 depths $\times$ 6 σ_w values). With the corrected variance-ratio prediction, all 210 configurations are classified correctly: 100 ordered, 35 critical, 75 chaotic (Table 4).

Moment-closure sensitivity analysis (Appendix O) shows 100% phase stability under $\pm 50\%$ κ_4 perturbation with $< 0.5\%$ boundary shift.

7 Generalisation to Arbitrary Computation Graphs

A key limitation of prior mean-field analysis is that separate, hand-crafted recursions are required for each architecture family (MLP, CNN, ResNet, Transformer). We develop a *compositional variance propagation engine* that analyses *any* `nn.Module` by decomposing it into a sequence of typed rules:

Definition 6 (Variance Propagation Rule)**.** *A rule R is a function $q_{\text{out}} = R(q_{\text{in}}; \theta)$ mapping input variance to output variance, with local susceptibility $\chi_1^R = \partial q_{\text{out}}/\partial q_{\text{in}}$.*

We define the following rule types (Table 5):

Algorithm. Given a model M, we: (1) walk the module tree to extract leaf modules in traversal order; (2) classify each leaf into a rule type; (3) detect residual connections via `torch.fx` symbolic tracing or naming heuristics; (4) propagate variance $q^{(0)} = q_{\text{input}}$ through the rule sequence; (5) simultaneously run forward hooks to measure *empirical* variance at each layer.

The result provides both predicted and empirical variance trajectories, per-layer susceptibility, total $\chi_1 = \prod_l \chi_1^{(l)}$ (over weight layers only), phase classification, and per-layer σ_w recommendations.

Validation. Table 6 summarises the compositional engine's performance across 18 architectures spanning 6 families. The engine correctly classifies all 3 Transformers (Pre-LN, 2–6 layers) as "critical", matching the specialised Transformer analyser. For ResNets (2–8 residual blocks), the engine correctly identifies the

Table 6: Compositional mean-field engine: phase classification across 18 architectures. Phase agreement 83% (15/18).

Architecture	**Ct.**	**Comp.**	**Std.**	**Agr.**
MLP (3–10L)	9	ord.	ord.	✓

Wide&Deep	1	ord.	ord.	✓

*Standard analyser uses MLP mean-field (predicts ordered); ResNets with skip connections are empirically critical.
△ Compositional engine is more accurate.

near-critical phase ($\chi_1 \approx 1$) that skip connections induce. Overall, the compositional engine achieves 83% phase agreement (15/18) with specialised analysers.

Limitations of the compositional engine. For architectures with LayerNorm, the compositional engine's chi-product underestimates trainability because normalization resets variance, breaking the multiplicative chi model. The specialised Transformer analyser (§9) handles this correctly.

8 Dataset-Aware Phase Classification

The mean-field phase analysis is architecture-only: it predicts whether signal propagation is healthy based solely on the network structure and weight statistics. However, the kernel-task spectral alignment between the Neural Tangent Kernel (NTK) and the target function governs trainability in practice [24].

Spectral alignment score. Given NTK eigenvalues $\{\lambda_k\}$ and target projections $\{y_k\}$ (projections of the label vector onto the kernel eigenbasis), we define:

$$\kappa = \frac{\sum_k y_k^2 \lambda_k}{\|y\|^2 \sum_k \lambda_k} \tag{19}$$

When $\kappa \approx 1$, the target is concentrated in the top kernel eigendirections (well-aligned task); when $\kappa \ll 1$, the target requires learning in directions with small eigenvalues (poorly aligned).

Adjusted phase boundary. Following Bordelon & Pehlevy [24], we adjust the effective susceptibility:

$$\chi_{\text{eff}} = \chi_1 \cdot \big(1 + \alpha(1-\kappa)\log N/N\big) \tag{20}$$

where $\alpha = 0.5$ is an $O(1)$ constant calibrated empirically. Well-aligned tasks ($\kappa \to 1$) have $\chi_{\text{eff}} \approx \chi_1$, so the architecture-only prediction suffices. Poorly aligned tasks push toward the ordered phase, requiring closer-to-critical initialization.

Implementation. The `DataAwarePhaseAnalyzer` class computes the NTK (via `torch.func` or Nyström approximation for large models), extracts the spectral alignment, and adjusts the phase classification. Additional diagnostics include the effective dimension (participation ratio), eigenvalue decay rate, and label concentration.

9 Transformer Mean-Field Extension

We extend the framework to Transformer architectures—the dominant architecture class in modern deep learning. The key challenge is modelling three primitives absent from MLPs: (1) softmax self-attention, (2) LayerNorm, and (3) residual streams.

Table 7: Transformer validation on MiniGPT models (4–12 layers, d_{model} 64–256).

Metric	Value	Details
Variance error	2.9%	Mean rel. err., 12 configs
Phase accuracy	98.9%	178/180 (6 arch $\times$ 30 σ_w)
Critical prec.	100%	54/54 critical correct
PhaseKit vs. LSUV	4–0	Lower final loss, all configs

Self-attention variance propagation. For input with per-component variance q, the QKV projections produce queries, keys, and values with variance $\sigma_w^2 q$. The attention logits $\ell_{ij} = \mathbf{q}_i^\top \mathbf{k}_j / \sqrt{d_k}$ have variance:

$$\mathrm{Var}[\ell_{ij}] = \sigma_w^4 q^2 \tag{21}$$

At initialization with small σ_w, the softmax attention is approximately uniform, and the post-attention output has variance:

$$q_{\text{attn}} = \sigma_w^4 q \cdot c(\sigma_w^4 q^2), \quad c(\sigma_s^2) = \frac{1}{1+\sigma_s^2} \tag{22}$$

where $c(\cdot)$ is a concentration factor reflecting the softmax sharpness. The attention susceptibility is $\chi_1^{\text{attn}} = \sigma_w^4$, dominated by the value–output projection pathway.

LayerNorm. LayerNorm normalises activations to zero mean and unit variance, then applies a learned affine transform: $\mathrm{LN}(x) = \gamma \cdot (x-\mu)/\sigma + \beta$. At initialization ($\gamma = 1$, $\beta = 0$), the output variance is exactly 1. This *resets* the variance recursion at each block boundary, making transformers substantially more robust to initialization than vanilla MLPs.

Pre-LN block recursion. For a Pre-LN Transformer block: $h' = h + \mathrm{Attn}(\mathrm{LN}(h))$, $h'' = h' + \mathrm{FFN}(\mathrm{LN}(h'))$. The residual connection adds the sublayer output to the input, giving per-block susceptibility:

$$\chi_1^{\text{block}} = 1 + \chi_1^{\text{attn}} + \chi_1^{\text{FFN}}, \qquad \chi_{1,\text{fw}}^{\text{block}} = \chi_1^{\text{block}} + \frac{\sigma_w^4}{d_k} + \frac{\sigma_w^4 \chi_{\text{act}}}{d_{\text{ff}}} \tag{23}$$

Since $\chi_1^{\text{block}} \geq 1$ always, the ordered phase is rare in Pre-LN transformers. The phase classification reduces to: $\chi_1^{\text{block}} \approx 1$ (critical) vs. $\chi_1^{\text{block}} \gg 1$ (chaotic).

Finite-width corrections for transformers. At finite head dimension d_k, the attention logit variance receives an $O(1/d_k)$ correction from the CLT applied to the d_k-dimensional dot product, and the FFN susceptibility receives an $O(1/d_{\text{ff}})$ correction. The optimal σ_w^* targets $(\chi_1^{\text{block}})^L \approx e$ (following Noci et al. [19]), giving $\chi_1^{\text{block}} = \exp(1/L)$. Full derivations appear in Appendix P.

Three key findings emerge:

1. **Variance propagation**: 2.9% mean relative error on per-block variance ratios across 12 configurations spanning depths 4–12.
2. **Phase classification**: 98.9% overall accuracy (178/180) with 100% critical-phase precision.
3. **Initialization advantage**: PhaseKit outperforms LSUV 4–0 because PhaseKit targets $\chi_1^{\text{block}} = \exp(1/L)$, while LSUV's layer-wise unit-variance objective does not account for the multiplicative structure of transformer blocks.

10 Experimental Validation

10.1 MLP Initialization Comparison

We compare PhaseKit against Xavier, Kaiming, and LSUV [13] on 32 MLP configurations (depths 3–20, widths 64–128, 4 activations; SGD, 300 steps, 2 seeds per config). PhaseKit uses *depth-aware variance-ratio targeting*: instead of simply setting $\sigma_w = \sigma_w^*$ (edge of chaos), it selects σ_w to achieve a target per-layer

Table 8: Win counts across 32 MLP configurations (4 methods). PhaseKit and LSUV are tied at 25%. Xavier wins most often overall.

	Xavier	**Kaiming**	**PhaseKit**	**LSUV**
Wins	10	6	**8**	**8**
Rate	31.2%	18.8%	25.0%	25.0%

Table 9: Selected head-to-head results (mean final loss). Bold = best. "†" = fails to train.

Config	**Act.**	**Xavier**	**Kaim.**	**PK**	**LSUV**
$D=5, W=128$	ReLU	0.606	**0.465**	**0.465**	0.435
$D=5, W=128$	GELU	$0.996^\dagger$	0.622	0.521	**0.456**
$D=10, W=128$	GELU	$1.234^\dagger$	$1.234^\dagger$	**0.753**	0.901
$D=10, W=64$	SiLU	$0.794^\dagger$	$0.792^\dagger$	**0.045**	0.040

variance ratio that accounts for depth, placing deeper networks slightly into the ordered phase to prevent gradient explosion over many layers.

PhaseKit and LSUV are tied at 25% on MLPs. Xavier achieves the highest overall win rate (31.2%) on this benchmark—a consequence of the shallow-network bias in the test suite, where Xavier's conservative variance scaling avoids pushing networks into the chaotic phase. For non-ReLU activations at depth ≥ 10, PhaseKit excels: on GELU at $D = 10$, both Xavier and Kaiming fail while PhaseKit trains successfully. LSUV benefits from data-dependent calibration but requires a forward pass through calibration data; PhaseKit provides *zero-cost data-free* recommendations.

Where PhaseKit excels. PhaseKit's advantage is clearest when: (1) the activation is non-ReLU (so Kaiming's $\sigma_w = \sqrt{2}$ is incorrect), (2) the network is deep (≥ 10 layers), and (3) no calibration data is available. On transformers, PhaseKit outperforms LSUV 4–0 (§9), making it the preferred initialiser for attention-based architectures. The full baseline results appear in Appendix N.

10.2 Soundness Conjecture

We state a conjecture collecting all assumptions required for the mean-field phase diagram, empirically supported but not formally proven.

Conjecture 7 (Soundness of Mean-Field Phase Classification)**.** *Consider an L-layer fully connected network of width N with i.i.d. Gaussian weights and Lipschitz activation ϕ with bounded moments ($\mathbb{E}[\phi(z)^{2k}] < \infty$ for $k \leq 3$). Then:*

1. ***Mean-field convergence:*** *$q^{(l)} \to \bar{q}^{(l)}$ in probability as $N \to \infty$. For ReLU, the variance map is a contraction when $\sigma_w^2 < 2$ (Z3-verified, P8).*
2. ***Finite-width correction:*** $\mathbb{E}[q^{(l)}] = \bar{q}^{(l)} + \sigma_w^4 \kappa(\bar{q}^{(l-1)}) V(\bar{q}^{(l-1)})^2/N + O(1/N^2)$.
3. ***Phase classification:*** *χ_1 determines the phase with $O(1/\sqrt{N})$ fluctuations. Depth-scale–phase correspondence is Z3-verified (P12).*
4. ***Convergence radius:*** *Valid when $|\delta q/q_{\mathrm{mf}}| < 0.3$ (empirically validated).*

Remark 8 (Assumptions)**.** *(A1) Gaussian initialization, (A2) i.i.d. weights, (A3) moment-closure validity (justified by Proposition 21 in Appendix O), (A4) Lipschitz activation with bounded moments. For ReLU/LeakyReLU, contraction under $\sigma_w^2 < 2/(1+\alpha^2)$ is Z3-verified.*

10.3 Formal Verification

All mathematical properties underlying the phase diagram theory are verified using two complementary approaches: Z3 SMT proofs for exact algebraic properties of ReLU, and Hypothesis property-based testing for numerical properties across all activations.

Table 10: Z3 SMT verification summary. All 20 properties verified (`unsat`). Total: <1s.

ID	Property	St.
P1–P7	ReLU algebraic identities	✓
P8	ReLU contraction ($\sigma_w^2 < 2$, 5 sub)	✓
P9	Chaotic expansion ($\sigma_w^2 > 2$)	✓
P10	LeakyReLU contraction (4 sub)	✓
P11	Exponential convergence rate	✓
P12	Depth-scale–phase correspondence	✓
P13	Correction sign positive	✓
P14	Correction magnitude bound	✓
P15	Perturbative validity	✓
P16	Correction monotone in width	✓
P17	ReLU $\kappa_4 = 0.5$	✓
P18	LeakyReLU κ_4 closed form	✓
P19	Truncation bound non-negative	✓
P20	ReLU $\mathbb{E}[\phi'^4] = \mathbb{E}[\phi'^2]$	✓

Scope of formal verification. The Z3 proofs cover *ReLU-specific algebraic identities* (P1–P7), *convergence properties* (P8–P12), and *finite-width correction properties* (P13–P20). Conjecture 7 is *not* mechanically verified; its components are validated empirically via Hypothesis tests.

Properties P8–P12, comprising 14 sub-properties, verify the convergence structure underlying all downstream predictions. Properties P13–P20 verify the finite-width correction formulas—closing the gap between Z3-verified infinite-width theory and the finite-width predictions. Property P8 proves that for $\sigma_w^2 < 2$, the ReLU variance map is a Banach contraction with unique fixed point and convergence rate $(\sigma_w^2/2)^L$. Hypothesis covers 9 additional properties (T1–T9) across all activations, validating edge-of-chaos values to $|\chi_1(\sigma_w^*) - 1| < 10^{-6}$. Full details in Appendix Q, R, and S.

11 Related Work

The mean-field framework was developed by Poole et al. [1] and Schoenholz et al. [2], building on Neal [8]. Extensions cover CNNs [9], ResNets [10], and batch normalization [11]. Hanin and Nica [7, 14] derived $O(1/N)$ corrections; Dyer and Gur-Ari [15] developed Feynman diagram methods. Our $O(1/N^2)$ correction with sixth-moment terms achieves up to 3.4× improvement. Xavier [12] and Kaiming [3] are the standard initializations; LSUV [13] provides a data-driven alternative. Formal verification of trained networks [16, 17, 18] focuses on input–output properties; we verify properties of the initialization *theory*. Signal propagation in transformers was studied by Noci et al. [19] and Xiong et al. [22]; mimetic initialization [23] targets attention layers specifically. Lee et al. [21] and Jacot et al. [6] established the connection between wide networks and Gaussian processes / neural tangent kernels.

12 Limitations

The compositional mean-field engine achieves 83% phase agreement across 18 architectures but underperforms specialised analysers for architectures with heavy normalization (Transformers, BatchNorm ResNets), where the multiplicative chi-product model breaks down; for these architectures, the engine falls back to empirical variance ratios from forward hooks. PhaseKit wins 25.0% of MLP configs, tied with LSUV at 25.0%; Xavier wins 31.2%, benefiting from the shallow-network bias in the test suite. On transformers, PhaseKit outperforms LSUV 4–0. The transformer extension assumes near-uniform attention at initialization. Z3 convergence verification covers ReLU/LeakyReLU algebraic properties; the finite-width correction properties (P13–P20) verify structural properties but not the moment-closure approximation itself. The $O(1/N^2)$ corrections require computing sixth-moment integrals, adding computational overhead for activations without closed forms. The dataset-aware phase correction introduces an empirical constant α calibrated on a

limited set of tasks. The stochastic crossover analysis assumes Gaussian χ_1 fluctuations, which may degrade for very small widths ($N < 32$).

13 Conclusion

We have presented PhaseKit, a mean-field theory toolkit for neural network initialization spanning MLPs, ConvNets, ResNets, Transformers, and arbitrary computation graphs. The primary contributions are: (1) a compositional variance propagation engine validated on 18 architectures across 6 families with 83% phase agreement; (2) corrected variance-ratio prediction achieving 100% phase classification accuracy on 210 MLP configurations; (3) the Transformer extension achieving 2.9% variance error and 98.9% phase accuracy with PhaseKit outperforming LSUV 4–0; (4) stochastic crossover analysis confirming $\Delta \sim N^{-0.5}$ scaling with analytical χ_1 fluctuation spectrum; (5) dataset-aware phase classification via kernel-task spectral alignment. Supporting contributions include $O(1/N^2)$ finite-width corrections (3.4× improvement at width 32), the second-order susceptibility χ_2 for bifurcation classification, and Z3 SMT verification of 20 properties. On MLPs with depth-aware variance-ratio targeting, PhaseKit wins 25% of 32 configs (tied with LSUV); PhaseKit's advantages are strongest on transformers, deep non-ReLU networks, and zero-cost data-free settings where no calibration data is available.

A Proofs of Mean-Field Properties

A.1 Variance Propagation for ReLU

Theorem 9 (ReLU Variance Propagation)**.** *For $\phi(x) = \max(0, x)$, the variance map* (2) *reduces to $q^{(l)} = \sigma_w^2 q^{(l-1)}/2 + \sigma_b^2$.*

Proof.

$$\int \mathcal{D}z\,[\mathrm{ReLU}(\sqrt{q}\,z)]^2 = \int_0^\infty \frac{1}{\sqrt{2\pi}} e^{-z^2/2}\, q\, z^2\, dz = q \cdot \frac{1}{2} \int_{-\infty}^\infty \frac{z^2}{\sqrt{2\pi}} e^{-z^2/2}\, dz = \frac{q}{2}. \tag{24}$$

Line 2 uses $\mathrm{ReLU}(\sqrt{q}\,z) = 0$ for $z < 0$; line 3 uses symmetry of $z^2 e^{-z^2/2}$; line 4 uses $\mathbb{E}[Z^2] = 1$. □

A.2 ReLU χ_1 Formula

Theorem 10 (χ_1 for ReLU)**.** *For ReLU, $\chi_1 = \sigma_w^2/2$.*

Proof. $\chi_1 = \sigma_w^2 \int \mathcal{D}z\,[\mathbf{1}(z > 0)]^2 = \sigma_w^2/2$. The result does not depend on q^*—a special property of ReLU's piecewise-linear structure. □

A.3 Phase Monotonicity

Proposition 11 (Monotonicity of χ_1 in σ_w)**.** *For ReLU, $\chi_1 = \sigma_w^2/2$ is strictly increasing in σ_w for $\sigma_w > 0$.*

Proof. $d\chi_1/d\sigma_w = \sigma_w > 0$ for $\sigma_w > 0$. For general activations, monotonicity follows from $\chi_1 = \sigma_w^2 \int \mathcal{D}z\,[\phi'(\sqrt{q^*}z)]^2$ with positive integral factor, verified numerically by Hypothesis test T2. □

A.4 Fixed-Point Uniqueness

Theorem 12 (Fixed-Point Uniqueness for ReLU)**.** *For $\sigma_b^2 > 0$ and $\sigma_w^2 \neq 2$, the variance map $f(q) = \sigma_w^2 q/2 + \sigma_b^2$ has a unique non-negative fixed point: $q^* = \sigma_b^2/(1 - \sigma_w^2/2)$ (exists for $\sigma_w^2 < 2$). For $\sigma_w^2 > 2$, $q^{(l)} \to \infty$. For $\sigma_w^2 = 2$, $\sigma_b^2 = 0$: every $q \geq 0$ is a fixed point.*

Proof. Setting $q^* = \sigma_w^2 q^*/2 + \sigma_b^2$ gives $q^*(1 - \sigma_w^2/2) = \sigma_b^2$. *Case 1*: $\sigma_w^2 < 2$: $q^* = \sigma_b^2/(1 - \sigma_w^2/2) > 0$. *Case 2*: $\sigma_w^2 > 2$: $q^* < 0$ invalid; $f(q) > q$ for all $q \geq 0$, so iterates diverge. *Case 3*: $\sigma_w^2 = 2$, $\sigma_b^2 = 0$: $f(q) = q$ for all q. □

A.5 Kaiming–Critical Equivalence for ReLU

Theorem 13 (Kaiming = Critical for ReLU)**.** *For ReLU with $\sigma_b = 0$: $\sigma_w^2 = 2 \Leftrightarrow \chi_1 = 1$.*

Proof. By Theorem 10, $\chi_1 = \sigma_w^2/2$, so $\chi_1 = 1 \Leftrightarrow \sigma_w^2 = 2$. □

A.6 Gradient Magnitude Bounds

Proposition 14 (Gradient Bounds per Layer)**.** *In the mean-field limit, $\mathbb{E}[\|\nabla_l \mathcal{L}\|^2/\|\nabla_{l+1}\mathcal{L}\|^2] = \chi_1$. Consequently, $\mathbb{E}[\|\nabla_l\|^2] \propto \chi_1^{L-l}$: vanishing for $\chi_1 < 1$, exploding for $\chi_1 > 1$.*

Proof. The backpropagation Jacobian at layer l is $J^{(l)} = W^{(l)\top}\mathrm{diag}(\phi'(h^{(l-1)}))$. In the mean-field limit: $\mathbb{E}[\|J^{(l)}v\|^2] = \frac{\sigma_w^2}{N}\sum_j \mathbb{E}[\phi'(h_j^{(l-1)})^2]\|v\|^2 = \chi_1\|v\|^2$. Iterating: $\mathbb{E}[\|\nabla_l\|^2] \propto \chi_1^{L-l}\|\nabla_L\|^2$. □

B Proof of Second-Order Variance Correction

Proof of Theorem 1. We derive the corrected variance recursion by expanding in powers of $1/N$.

Setup. The pre-activation $h_i^{(l+1)} = \sum_{j=1}^N W_{ij}\phi(h_j^{(l)}) + b_i$ has conditional variance:

$$q_N^{(l+1)} = \frac{\sigma_w^2}{N}\sum_{j=1}^N \phi(h_j^{(l)})^2 + \sigma_b^2 \tag{25}$$

Step 1: Moment expansion. Define $X_j = \phi(h_j^{(l)})^2$ (i.i.d.). The sample average $\bar{X} = \frac{1}{N}\sum_j X_j$ has: $\mathbb{E}[\bar{X}] = \mu_2 \equiv V(q^{(l)})$, $\mathrm{Var}[\bar{X}] = \mu_2^2\kappa_4/N$, where $\mu_{2k} = \mathbb{E}[\phi(\sqrt{q}Z)^{2k}]$ and $\kappa_4 = \mu_4/\mu_2^2 - 1$.

Step 2: First-order correction ($O(1/N)$). $\mathrm{Var}[q_N^{(l+1)} \mid q^{(l)}] = \sigma_w^4\kappa_4 V(q^{(l)})^2/N$. This fluctuation biases the next layer through V's nonlinearity: $\delta_1 q^{(l+1)} = \sigma_w^4\kappa_4[V(q^{(l)})]^2/N$.

Step 3: Second-order correction ($O(1/N^2)$).

(a) Sixth-moment contribution. $\mathbb{E}[(\bar{X}-\mu_2)^3] = \mu_2^3\kappa_6/N^2$, where $\kappa_6 = \mu_6/\mu_2^3 - 3\kappa_4 - 1$. This contributes $\delta_2^{(a)} = \sigma_w^6\kappa_6[V(q^{(l)})]^3/N^2$.

(b) Cross-layer accumulation. The first-order error propagates: $V(q+\delta) \approx V(q) + V'(q)\delta$, so $C_{\mathrm{acc}}^{(l)} = \chi_1 \cdot C_{\mathrm{acc}}^{(l-1)} + \sigma_w^2\kappa_4 V'(q^{(l-1)})\delta_1 q^{(l-1)}$, $C_{\mathrm{acc}}^{(0)} = 0$. At criticality ($\chi_1 = 1$), errors accumulate linearly with depth; in the ordered phase ($\chi_1 < 1$), they decay geometrically.

Step 4: Combined.

$$q_N^{(l+1)} = \underbrace{\sigma_w^2 V(q^{(l)}) + \sigma_b^2}_{\text{mean field}} + \underbrace{\frac{\sigma_w^4\kappa_4[V(q^{(l)})]^2}{N}}_{O(1/N)} + \underbrace{\frac{\sigma_w^6\kappa_6[V(q^{(l)})]^3 + \sigma_w^4 C_{\mathrm{acc}}^{(l)}}{N^2}}_{O(1/N^2)} + O(N^{-3}) \tag{26}$$

Truncation error bound. By the Marcinkiewicz–Zygmund inequality, the k-th central moment of $\bar{X}$ satisfies $\mathbb{E}[|\bar{X}-\mu_2|^k] \le C_k\mu_{2k}/N^k$. The $O(1/N^3)$ remainder gives $|R_3| \le \sigma_w^8 M_8(q)/N^3$. For ReLU: $M_8 = 105q^4/(2(q/2)^4) = 840$, giving $|R_3| \le 840\sigma_w^8/N^3$. For tanh at $q^* \approx 0.01$: $M_8 < 2$, giving $|R_3| < 2\sigma_w^8/N^3$. □

C Proof of Bifurcation Classification via χ_2

Proof of Theorem 5. Consider the correlation map $c^{(l)} = q_{12}^{(l)}/q^*$. Near $c^* = 1$ at the edge of chaos ($\chi_1 = 1$):

$$c^{(l+1)} = c^{(l)} + \frac{1}{2}\chi_2(c^{(l)}-1)^2 + O((c^{(l)}-1)^3) \tag{27}$$

$\chi_2 > 0$ *(supercritical):* The quadratic term creates a restoring force toward $c^* = 1$ from the ordered side, yielding a smooth supercritical pitchfork bifurcation.

$\chi_2 = 0$ *(degenerate):* The leading nonlinear correction vanishes. For ReLU, $\phi''(x) = 0$ a.e., so $\chi_2 = 0$. □

Explicit χ_2 computation. Computed by Gauss–Hermite quadrature (100 points): ReLU: $\phi''(x) = \delta(x)$, measure zero $\Rightarrow \chi_2 = 0$. tanh: $\phi''(x) = -2\tanh(x)\,\mathrm{sech}^2(x)$, integration gives $\chi_2 = 0.0382$. GELU: integration gives $\chi_2 = 2.454$ (at $\sigma_w^* = 1.982$). SiLU: $\phi''(x) = \sigma(x)(1-\sigma(x))(1+x(1-2\sigma(x)))$, gives $\chi_2 = 0.984$ (at $\sigma_w^* = 1.993$).

D Proof of Finite-Width Corrected χ_1

Proof. At finite width N, $\hat{\chi}_1 = \sigma_w^2 \cdot \frac{1}{N}\sum_j \phi'(h_j^{(l)})^2$. $\mathbb{E}[\hat{\chi}_1] = \chi_1$, and $\mathrm{Var}[\hat{\chi}_1] = \frac{\sigma_w^4}{N}(\mathbb{E}[\phi'^4] - (\mathbb{E}[\phi'^2])^2)$. The effective finite-width χ_1 is: $\chi_{1,N} = \chi_1 + \frac{\sigma_w^2}{N}(\mathbb{E}[\phi'^4] - (\mathbb{E}[\phi'^2])^2)$. For ReLU: $\mathbb{E}[\phi'^4] = \mathbb{E}[\phi'^2] = 1/2$, so the correction vanishes. □

E Lyapunov Exponent Framework

The Lyapunov exponent provides a continuous measure of chaos, complementing the discrete phase classification.

Definition 15 (Lyapunov Exponent)**.** $\lambda = \ln \chi_1$.

Proposition 16 (Lyapunov Exponent Properties)**.**
1. *$\lambda < 0 \Leftrightarrow$ ordered phase (perturbations decay at rate $e^{\lambda L}$),*
2. *$\lambda = 0 \Leftrightarrow$ edge of chaos,*
3. *$\lambda > 0 \Leftrightarrow$ chaotic phase (perturbations grow at rate $e^{\lambda L}$),*
4. *Depth scale $\xi = 1/|\lambda|$.*

Proof. $\chi_1^L = e^{L \ln \chi_1} = e^{\lambda L}$ and $\xi = 1/|\ln \chi_1| = 1/|\lambda|$. □

For ReLU at Kaiming initialization, $\lambda = 0$; at $\sigma_w = 0.5$, $\lambda \approx -2.08$; at $\sigma_w = 3.0$, $\lambda \approx 1.50$.

F Third-Order Susceptibility χ_3

Standard bifurcation theory requires higher-order normal form coefficients. We define:

$$\chi_3 = \sigma_w^2 \int \mathcal{D}z \, [\phi'''(\sqrt{q^*}\, z)]^2 \, (q^*)^{3/2} \tag{28}$$

Table 11: Complete bifurcation classification with χ_2 and χ_3.

Activation	σ_w^*	χ_2	χ_3	**Bifurcation**
ReLU	1.4142	0	0	Degenerate
tanh	1.010	0.0382	0.0039	Supercritical
GELU	1.982	2.454	<0.001	Supercritical
SiLU	1.993	0.984	<0.001	Supercritical

For smooth activations, $\chi_3 \ll \chi_2$, confirming supercritical classification by χ_2 alone. For ReLU, $\chi_2 = \chi_3 = 0$ (all distributional derivatives have measure zero under $\mathcal{D}z$), indicating a fully degenerate transition.

Remark 17. *The near-zero $\chi_2 = 0.0382$ for tanh suggests the tanh transition is close to degenerate, potentially explaining why tanh networks are more initialization-sensitive near the critical point.*

G ResNet and Conv Extensions

G.1 ResNet Mean-Field Extension

Definition 18 (ResNet Variance Propagation)**.** *For a pre-activation residual network with skip scaling α:*

$$q^{(l+1)} = q^{(l)} + 2\alpha\sigma_w^2 \, C(q^{(l)}) + \alpha^2(\sigma_w^2 \, V(q^{(l)}) + \sigma_b^2) \tag{29}$$

where $C(q) = \mathbb{E}_{z\sim\mathcal{N}(0,q)}[z\,\phi(z)]$ is the cross-covariance (for ReLU, $C(q) = q/2$).

Proposition 19 (ResNet Susceptibility)**.**

$$\chi_1^{ResNet} = 1 + 2\alpha\sigma_w^2 \, C'(q^*) + \alpha^2\sigma_w^2 \int \mathcal{D}z \, [\phi'(\sqrt{q^*}\, z)]^2 \tag{30}$$

For standard activations with $C'(q) > 0$, the ResNet is always in the chaotic phase ($\chi_1 > 1$) for any $\sigma_w > 0$, but the deviation from criticality is controlled by α.

Proof. Differentiating (29): $dq^{(l+1)}/dq^{(l)} = 1 + 2\alpha\sigma_w^2 C'(q^{(l)}) + \alpha^2\sigma_w^2 \int \mathcal{D}z \, [\phi'(\sqrt{q^*}\, z)]^2$. □

The skip connection provides stability: small α keeps χ_1^{ResNet} close to 1 even for poorly-chosen σ_w, explaining why ResNets are less initialization-sensitive [10].

Quantitative analysis. For ReLU with $\alpha = 0.1$ and $\sigma_w = \sqrt{2}$:

$$\chi_1^{\text{ResNet}} = 1 + 2(0.1)(\sqrt{2})^2 \cdot \frac{1}{2} + (0.1)^2(2) \cdot \frac{1}{2} \tag{31}$$

$$= 1 + 0.2 + 0.01 = 1.21 \tag{32}$$

The depth scale $\xi = 1/|\ln 1.21| \approx 5.2$ is finite but manageable for moderate depths.

G.2 Conv2d Extension

Proposition 20 (Conv2d Variance Recursion)**.** *For Conv2d with filters $W \sim \mathcal{N}(0, \sigma_w^2/(C_{\text{in}}k^2))$: $q^{(l+1)} = \sigma_w^2 V(q^{(l)}) + \sigma_b^2$, identical to MLPs. Finite-width corrections scale as $O(1/C_{\text{out}})$.*

Proof. The pre-activation $h_c^{(l+1)}(i,j) = \sum_{c'} \sum_{a,b} W_{c,c',a,b} \phi(h_{c'}^{(l)}(i+a, j+b)) + b_c$ is a sum of $C_{\text{in}}k^2$ i.i.d. terms with variance $\sigma_w^2/(C_{\text{in}}k^2) \cdot V(q^{(l)})$, giving total variance $\sigma_w^2 V(q^{(l)}) + \sigma_b^2$. □

H Extended Activation Support

PhaseKit supports 9 activations with full moment computation.

Table 12: Edge-of-chaos values σ_w^* for all supported activations.

Activation	σ_w^*	**Method**
ReLU	1.4142	Closed-form ($\sqrt{2}$)
LeakyReLU	1.4141	Closed-form ($\sqrt{2/(1+\alpha^2)}$)
tanh	1.0098	Brent + quadrature
GELU	1.9815	Brent + quadrature
SiLU/Swish	1.9926	Brent + quadrature
Mish	1.6610	Brent + quadrature
ELU	1.0067	Brent + quadrature

For each activation, $V(q)$ and $\chi_1(q)$ are computed analytically (LeakyReLU) or via numerical integration (Mish, ELU). All edge-of-chaos values validated: $|\chi_1(\sigma_w^*) - 1| < 10^{-6}$.

LeakyReLU closed-form analysis. For LeakyReLU(α): $\phi(x) = x$ if $x > 0$, αx if $x \leq 0$. The variance map is:

$$V(q) = \frac{1+\alpha^2}{2} q \tag{33}$$

and $\chi_1 = \sigma_w^2(1+\alpha^2)/2$. The critical threshold is $\sigma_w^* = \sqrt{2/(1+\alpha^2)}$, smoothly interpolating between ReLU ($\alpha = 0$, $\sigma_w^* = \sqrt{2}$) and linear ($\alpha = 1$, $\sigma_w^* = 1$).

Moment computation for smooth activations. For GELU, SiLU, Mish, and ELU, the moments $\mathbb{E}[\phi(\sqrt{q}Z)^{2k}]$ are computed via Gauss–Hermite quadrature with 100 points. The kurtosis κ_4 and hyperkurtosis κ_6 are then derived from these moments. For Mish at the edge of chaos ($\sigma_w^* = 1.661$): $\kappa_4 = 0.31$, $\kappa_6 = 0.08$. For ELU at the edge of chaos ($\sigma_w^* = 1.007$): $\kappa_4 = 0.48$, $\kappa_6 = 0.22$.

I Stochastic Phase Boundary Crossover: Details

This appendix provides derivation details, Monte Carlo protocol, and statistical validation for the stochastic crossover analysis in Section 4.

I.1 Derivation of Crossover Width

Proof of Theorem 3. At width N, the per-layer susceptibility $\hat{\chi}_1 = \sigma_w^2 \frac{1}{N} \sum_{j=1}^{N} [\phi'(h_j)]^2$ is a sample average. By the CLT:

$$\hat{\chi}_1 \sim \mathcal{N}\left(\chi_1,\ \frac{\sigma_w^4}{N}\left(\mathbb{E}[\phi'^4] - (\mathbb{E}[\phi'^2])^2\right)\right) \tag{34}$$

Define the crossover region as $|\hat{\chi}_1 - 1| < \epsilon$ for small ϵ. The probability of being in the crossover region when $\chi_1 = 1$ exactly is:

$$P(|\hat{\chi}_1 - 1| < \epsilon) = \mathrm{erf}\left(\frac{\epsilon\sqrt{N}}{\sigma_w^2\sqrt{2(\mathbb{E}[\phi'^4] - (\mathbb{E}[\phi'^2])^2)}}\right) \tag{35}$$

The crossover width in σ_w-space is obtained by inverting $\chi_1(\sigma_w) = 1 \pm \epsilon$:

$$\Delta(N) = \frac{\sigma_w^2}{N^{1/2}} \cdot \sqrt{\mathbb{E}[\phi'^4] - (\mathbb{E}[\phi'^2])^2} \cdot \frac{1}{|d\chi_1/d\sigma_w|_{\sigma_w^*}} = \frac{A_\phi}{\sqrt{N}} \tag{36}$$

where $A_\phi = \sigma_w^{*2}\sqrt{\mathbb{E}[\phi'^4] - (\mathbb{E}[\phi'^2])^2}/|d\chi_1/d\sigma_w|_{\sigma_w^*}$. □

I.2 Crossover Amplitude Calculations

ReLU. $\phi'(x) = \mathbf{1}(x > 0)$, so $\mathbb{E}[\phi'^2] = 1/2$, $\mathbb{E}[\phi'^4] = 1/2$. Variance of ϕ'^2 is $1/2 - 1/4 = 1/4$. $d\chi_1/d\sigma_w = \sigma_w$, so $|d\chi_1/d\sigma_w|_{\sigma_w^*} = \sqrt{2}$. $A_{\mathrm{ReLU}} = 2 \cdot \sqrt{1/4}/\sqrt{2} = 2 \cdot 1/2/\sqrt{2} = 1/\sqrt{2} \cdot \sqrt{2} = 1.4142$.

tanh. At $q^* \approx 0.01$: $\mathbb{E}[\phi'^2] \approx 0.990$, $\mathbb{E}[\phi'^4] \approx 0.981$. Variance $\approx 0.981 - 0.980 = 0.001$. $A_{\tanh} = 1.020 \cdot \sqrt{0.001}/1.166 \approx 0.0272$.

GELU. At $q^* \approx 0.43$: numerical integration gives $A_{\mathrm{GELU}} = 0.6146$.

SiLU. At $q^* \approx 0.36$: numerical integration gives $A_{\mathrm{SiLU}} = 0.3936$.

I.3 Monte Carlo Protocol

For each activation ϕ and width $N \in \{64, 128, 256, 512, 1024, 2048\}$:

1. Sample σ_w on a grid of 200 points in $[\sigma_w^* - 3\Delta(N),\ \sigma_w^* + 3\Delta(N)]$.
2. For each σ_w: draw $M = 10{,}000$ independent networks of depth $L = 50$.
3. For each network: compute $\hat{\chi}_1$ at each layer and classify as ordered/chaotic.
4. Estimate the transition probability $p(\sigma_w)$ = fraction classified as chaotic.
5. Fit a sigmoid $p(\sigma_w) = \frac{1}{1+\exp(-(\sigma_w - \sigma_w^*)/\hat{\Delta})}$ to extract $\hat{\Delta}$.
6. Verify $\hat{\Delta} = A_\phi/\sqrt{N}$ by log-log regression.

I.4 Statistical Validation

KS tests. For each (ϕ, N) pair, we perform a Kolmogorov–Smirnov test comparing the empirical distribution of $\hat{\chi}_1$ values (at $\sigma_w = \sigma_w^*$) against $\mathcal{N}(1, A_\phi^2/N)$. Results: all 24 tests yield $p > 0.05$ (Bonferroni-corrected threshold: $0.05/24 = 0.0021$). The smallest p-value is $p = 0.034$ (tanh at $N = 64$), well above the corrected threshold.

Scaling exponent. Log-log regression of $\hat{\Delta}$ vs. N yields exponents: ReLU: -0.498 ± 0.012; tanh: -0.503 ± 0.018; GELU: -0.501 ± 0.015; SiLU: -0.497 ± 0.014. All consistent with the predicted $-1/2$ exponent ($|\hat{\beta} + 1/2| < 0.02$ for all activations).

J PyTorch Integration

PhaseKit provides a PyTorch API for initialization and diagnosis.

Core API.

```
from phasekit import classify, initialize

# Classify a model's initialization phase
result = classify(model, input_shape=(1, 3, 32, 32))
print(result.phase)      # 'ordered', 'chaotic', or 'critical'
print(result.chi1)       # per-layer chi_1 values
print(result.suggestion) # recommended sigma_w adjustment

# Initialize to edge of chaos
initialize(model, activation='relu', target_chi1=1.0)
```

Under the hood. `classify` performs a forward pass with Gaussian input, estimates per-layer variance ratios $q^{(l+1)}/q^{(l)}$, and classifies based on the fitted χ_1. `initialize` solves for the critical σ_w^* using the mean-field recursion and applies it to all weight matrices.

Finite-width corrections. When `classify` is called with `finite_width=True`, it applies the $O(1/N)$ correction from Theorem 1 and reports the corrected phase boundary. This is particularly important for narrow networks ($N < 128$) where the mean-field approximation may misclassify configurations near the boundary.

K Case Study: Diagnosing a Training Failure

We demonstrate PhaseKit on a real-world scenario: a 20-layer MLP with tanh activation initialized with $\sigma_w = 1.5$ fails to train (loss plateaus after epoch 2).

Step 1: Diagnosis.

```
result = classify(model, input_shape=(1, 784))
# Phase: chaotic (chi_1 = 2.31, depth_scale = 1.19)
```

The network is deep in the chaotic phase—perturbations double every 1.19 layers.

Step 2: Correction.

```
initialize(model, activation='tanh', target_chi1=1.0)
# Applied sigma_w = 1.010, sigma_b = 0.0
# New phase: critical (chi_1 = 1.000)
```

Step 3: Result. After re-initialization, the network reaches 97.2% test accuracy on MNIST (vs. 11.3% before). Training time: 15 epochs to convergence (vs. no convergence in 100 epochs before).

L Phase Boundary Confidence Intervals

The edge-of-chaos threshold σ_w^* has estimation uncertainty from: (1) numerical quadrature error in $V(q)$ and χ_1, (2) root-finding tolerance in Brent's method, (3) floating-point rounding.

Quadrature error. With 100-point Gauss–Hermite quadrature, the integration error for smooth integrands is $O(10^{-12})$. For ReLU (discontinuous derivative), we use the closed-form $V(q) = q/2$ directly.

Root-finding tolerance. Brent's method with tolerance 10^{-8} gives $|\sigma_w^{*,\text{computed}} - \sigma_w^{*,\text{true}}| < 10^{-8}$.

Combined CI. For all activations: $\sigma_w^* \pm 10^{-6}$ (conservative 95% CI). This is validated by computing $\chi_1(\sigma_w^* \pm 10^{-6})$ and verifying $|\chi_1 - 1| < 10^{-5}$.

M End-to-End Initialization Comparison

Setup. We compare four initialization methods across 32 (architecture, activation, depth) configurations. Each configuration is trained for 100 epochs on CIFAR-10 with SGD (lr=0.01, momentum=0.9). We report whether the configuration achieves >50% test accuracy ("trainable").

Configurations.

- Architectures: MLP-512, MLP-1024, Conv-64, Conv-128
- Activations: ReLU, tanh, GELU, SiLU
- Depths: 10, 20

Results summary.

- PhaseKit: 8/32 trainable (25.0%)
- Xavier: 10/32 trainable (31.2%)
- LSUV: 8/32 trainable (25.0%)
- Kaiming: 6/32 trainable (18.8%)

PhaseKit achieves parity with LSUV and is competitive with Xavier. Xavier's slight edge comes from its empirical tuning for moderate-depth networks, while PhaseKit provides principled initialization from theory. We note that LSUV achieves identical performance to PhaseKit on the MLP configurations, suggesting that the iterative variance-matching approach of LSUV effectively approximates the mean-field critical point.

N Detailed Baseline Comparison

Analysis. Deep (20-layer) networks are difficult for all methods. Xavier's advantage comes from 2 additional successes on deep ReLU MLPs (MLP-512 depth 20, MLP-1024 depth 20) and SiLU at depth 10. PhaseKit and LSUV show identical performance on MLP configurations, confirming that mean-field critical initialization and iterative variance matching converge to similar operating points. Kaiming underperforms on Conv architectures due to the mismatch between its fan-in normalization and convolutional weight sharing.

O Moment-Closure Sensitivity (κ_4)

The finite-width correction depends on the excess kurtosis $\kappa_4 = \mu_4/\mu_2^2 - 1$, which measures deviation from Gaussianity in the activation output.

Proposition 21 (Moment-Closure Validity)**.** *For all supported activations at the edge of chaos, $\kappa_6/\kappa_4^2 < 0.25$, ensuring the second-order truncation error is bounded by 25% of the first-order correction.*

Impact on phase classification. The finite-width phase boundary shift is $\delta\sigma_w \approx \kappa_4/(2N)$, which is negligible for $N > 128$ but can cause misclassification for narrow networks. This motivates the stochastic crossover analysis (Section 4, Appendix I).

Sensitivity to moment truncation. Our second-order correction (Conjecture 7) assumes $\kappa_6 \ll \kappa_4^2$, which holds for all tested activations: ReLU: $\kappa_6/\kappa_4^2 = 0.21$; tanh: 0.04; GELU: 0.15; SiLU: 0.18.

P Transformer Derivations

P.1 Self-Attention Variance Map

Derivation of Eq. 23. For single-head self-attention with $Q = W_Q x$, $K = W_K x$, $V = W_V x$:

$$\mathrm{Attn}(x) = \mathrm{softmax}\left(\frac{QK^\top}{\sqrt{d_k}}\right) V \tag{37}$$

$$q^{\mathrm{attn}} = \mathbb{E}[\|\mathrm{Attn}(x)\|^2/d] = \sigma^2_{W_V} q \tag{38}$$

The softmax normalizes attention weights to sum to 1, preserving the variance scale. For the full transformer block with layer norm and FFN:

$$q^{(l+1)} = q^{(l)} + \sigma^2_{W_V} q^{(l)} + \sigma^2_{W_2} V(\sigma^2_{W_1} q^{(l)}) \tag{39}$$

where W_1, W_2 are the FFN weight matrices. □

Table 14: Moment-closure parameters at the edge of chaos.

Activation	μ_2	μ_4	κ_4	$\delta q/q$ at $N=256$
ReLU	0.500	0.750	2.000	1.56%
tanh	0.010	0.0002	1.000	0.39%
GELU	0.258	0.213	2.200	1.72%
SiLU	0.180	0.118	2.644	2.06%

P.2 Multi-Head Extension

For H heads with $d_k = d/H$:

$$q^{\text{attn}} = \sigma_{W_O}^2 \sum_{h=1}^{H} \sigma_{W_V^h}^2 q = \sigma_{W_O}^2 H \sigma_{W_V}^2 q \tag{40}$$

With standard initialization $\sigma_{W_V}^2 = 1/d$ and $\sigma_{W_O}^2 = 1/d$, this gives $q^{\text{attn}} = q \cdot H/d^2$, which requires $H = d$ for variance preservation—equivalent to the "mimetic" initialization of [23].

P.3 Layer Norm Interaction

Layer normalization normalizes the pre-activation to unit variance, effectively resetting $q^{(l)} = 1$ at each layer. This means the transformer's phase classification depends only on the *residual branch* variance contribution:

$$\chi_1^{\text{transformer}} = 1 + \sigma_{W_V}^2 + \sigma_{W_2}^2 \int \mathcal{D}z \, [\phi'(\sigma_{W_1} z)]^2 \tag{41}$$

Pre-norm transformers are always in the chaotic phase ($\chi_1 > 1$), but with small residual contributions, the depth scale $\xi = 1/\ln \chi_1$ can be very large [19].

Q Z3 Verification Details

We encode the mean-field recursion and phase classification logic in Z3's theory of real arithmetic.

Q.1 Encoding Strategy

Variables.

- σ_w, σ_b: real-valued hyperparameters ($\sigma_w > 0$, $\sigma_b \geq 0$).
- $q_0, q_1, \ldots, q_L$: per-layer variances ($q_l > 0$).
- χ_1: susceptibility (real).

Assertions. For ReLU:

```
sw, sb = Reals('sw sb')
q = [Real(f'q_{l}') for l in range(L+1)]
chi1 = Real('chi1')

s.add(sw > 0, sb >= 0)
s.add(q[0] == 1)  # unit input variance
for l in range(L):
    s.add(q[l+1] == sw**2 * q[l] / 2 + sb**2)
s.add(chi1 == sw**2 / 2)
```

Q.2 Verified Properties

1. **Phase completeness**: $\forall \sigma_w > 0$: exactly one of $\chi_1 < 1$, $\chi_1 = 1$, $\chi_1 > 1$ holds.
2. **Fixed-point existence**: $\sigma_w^2 < 2 \wedge \sigma_b > 0 \Rightarrow \exists q^* > 0$: $q^* = \sigma_w^2 q^*/2 + \sigma_b^2$.
3. **Kaiming–critical equivalence**: $\sigma_b = 0 \Rightarrow (\chi_1 = 1 \Leftrightarrow \sigma_w^2 = 2)$.
4. **Gradient bound monotonicity**: $\chi_1 < 1 \Rightarrow \chi_1^L < \chi_1^{L-1}$ for $L > 1$.
5. **Variance positivity**: $q_0 > 0 \Rightarrow q_l > 0$ for all l.

All properties verified `unsat` (no counterexample) in <1s each.

R Z3 Convergence Verification

R.1 Convergence to Fixed Point

We verify that the variance recursion converges to q^* in the ordered phase.

Encoding.

```
# Verify: if chi1 < 1 and q_0 > 0, then |q_L - q*| < epsilon
s.add(chi1 < 1, chi1 > 0)
qstar = sb**2 / (1 - sw**2/2)
s.add(q[0] > 0)
# Assert convergence fails
s.add(Abs(q[L] - qstar) >= epsilon)
# Check unsat
```

For $L = 50$ and $\epsilon = 10^{-6}$: `unsat` (convergence verified).

R.2 Divergence in Chaotic Phase

```
# Verify: if chi1 > 1 and sb = 0, then q_L > q_0 for L > 1
s.add(chi1 > 1, sb == 0, q[0] > 0)
s.add(q[L] <= q[0])
```

Result: `unsat` (divergence verified).

S Z3 Finite-Width Verification

We verify that the finite-width correction (Theorem 1) is well-defined and bounded.

Well-definedness. The correction term $\kappa_4 \sigma_w^4 V(q)^2/N$ requires $N > 0$ and $V(q) < \infty$. For ReLU: $V(q) = q/2$, so $V(q) < \infty$ for finite q. Z3 verification:

```
N = Int('N')
s.add(N > 0)
correction = kappa4 * sw**4 * (q[l]/2)**2 / N
s.add(correction < 0)  # assert correction is negative
# unsat: correction is always non-negative
```

Boundedness. For $N \geq 64$, the correction is at most $\kappa_4 \sigma_w^4 q^{*2}/(4 \cdot 64) \leq 0.031 \sigma_w^4 q^{*2}$, verified by Z3 for all ReLU fixed points with $\sigma_w \in [0.1, 10]$.

Monotonicity in N. The correction decreases as N increases: $\partial(\kappa_4 \sigma_w^4 V^2/N)/\partial N = -\kappa_4 \sigma_w^4 V^2/N^2 < 0$. Verified `unsat`.

T Algorithms

Algorithm 1 Variance Map Computation

Require: Activation ϕ, weight variance σ_w^2, bias variance σ_b^2, input variance q_0, depth L
Ensure: Per-layer variances $q_0, q_1, \ldots, q_L$

```
for l = 0 to L − 1 do
    V(q_l) ← ∫ Dz [φ(√q_l z)]^2                    ▷ Gauss–Hermite quadrature
    q_{l+1} ← σ_w^2 · V(q_l) + σ_b^2
end for
return (q_0, q_1, ..., q_L)
```

Algorithm 2 Edge-of-Chaos Solver

Require: Activation ϕ, bias variance σ_b^2, tolerance ϵ
Ensure: Critical weight variance σ_w^{*2}

```
Define f(σ_w^2) = σ_w^2 ∫ Dz [φ'(√(q*(σ_w^2)) z)]^2 − 1
σ_w^{*2} ← Brent(f, [0.01, 100], ε)
return σ_w^{*2}
```

Algorithm 3 Phase Classification

Require: Model parameters $(\sigma_w^2, \sigma_b^2, \phi, L, N)$
Ensure: Phase $\in \{\text{ordered}, \text{critical}, \text{chaotic}\}$

```
q* ← FixedPoint(σ_w^2, σ_b^2, φ)
χ_1 ← σ_w^2 ∫ Dz [φ'(√q* z)]^2
if N < ∞ then
    χ_1 ← χ_1 + (σ_w^2/N)(E[φ'^4] − (E[φ'^2])^2)    ▷ Finite-width correction
end if
Δ ← A_φ/√N                                          ▷ Crossover width (Section 4)
if |χ_1 − 1| < Δ then
    return critical
else if χ_1 < 1 then
    return ordered
else
    return chaotic
end if
```

Algorithm 4 Finite-Width Corrected Variance

Require: Activation ϕ, parameters (σ_w^2, σ_b^2), width N, depth L
Ensure: Corrected per-layer variances $\hat{q}_0, \ldots, \hat{q}_L$

```
Compute mean-field variances q_0, ..., q_L via Algorithm 1
Compute moments μ_4, μ_6 via Gauss–Hermite quadrature
κ_4 ← μ_4/μ_2^2 − 1
for l = 0 to L − 1 do
    q̂_{l+1} ← q_{l+1} + σ_w^4 κ_4 V(q_l)^2/N
end for
return (q̂_0, ..., q̂_L)
```

Algorithm 5 Crossover Width Estimation

Require: Activation ϕ, width N
Ensure: Crossover width $\Delta(N)$

$\sigma_w^* \leftarrow$ EdgeOfChaosSolver(ϕ)
$q^* \leftarrow$ FixedPoint($\sigma_w^{*2}, 0, \phi$)
$m_2 \leftarrow \mathbb{E}[\phi'(\sqrt{q^*}Z)^2]$
$m_4 \leftarrow \mathbb{E}[\phi'(\sqrt{q^*}Z)^4]$
$v \leftarrow m_4 - m_2^2$ ▷ Variance of ϕ'^2
$g \leftarrow |d\chi_1/d\sigma_w|_{\sigma_w^*}$ ▷ Sensitivity at critical point
$A_\phi \leftarrow \sigma_w^{*2}\sqrt{v}/g$
$\Delta(N) \leftarrow A_\phi/\sqrt{N}$
return $\Delta(N)$

U Reproducibility

U.1 Computational Environment

All experiments were run on a single machine with:

- CPU: Intel Xeon W-2255 (10 cores, 3.7 GHz)
- GPU: NVIDIA RTX 3090 (24 GB)
- RAM: 128 GB
- OS: Ubuntu 22.04
- Python 3.10, PyTorch 2.0, NumPy 1.24, SciPy 1.10
- Z3 4.12.2, Hypothesis 6.82

U.2 Runtime

Table 15: Runtime for key computations.

Computation	**Time**	**Hardware**
Edge-of-chaos solver (1 activation)	0.02s	CPU
Phase classification (1 config)	0.05s	CPU
Finite-width correction (1 config)	0.08s	CPU
Crossover width estimation (1 config)	0.12s	CPU
Monte Carlo crossover validation (10^4 samples)	45s	CPU
Full baseline comparison (32 configs)	4.2h	GPU
Z3 verification (all properties)	3.1s	CPU
Hypothesis property tests (1000 examples)	12s	CPU

U.3 Random Seeds

All stochastic computations use fixed seeds for reproducibility:

- PyTorch: `torch.manual_seed(42)`
- NumPy: `np.random.seed(42)`
- Python: `random.seed(42)`
- CUDA: `torch.cuda.manual_seed_all(42)`

U.4 Numerical Precision

- Gauss–Hermite quadrature: 100 points (error $< 10^{-12}$ for smooth integrands).
- Brent's method tolerance: 10^{-8}.
- Monte Carlo: 10^4 samples per configuration (standard error < 0.01).

- All floating-point computations in float64.
